DISTRIBUTED AUTHENTICATION FRAMEWORK STACK

Field of the Invention

[0001] This invention relates to computer-based communication systems and more particularly to methods and systems for providing authentication to end user applications.

Background

[0002] The rapid advance in computer-based communications systems, such as the public Internet and private Intranet, has meant that more and more data is being transmitted via this medium. For much of this data, including financial and health records security is extremely important. As a result, considerable development has gone into creating security mechanisms. Concomitant with these developments is the effort by hackers and other system attackers to find ways to break the security mechanisms. One way to reduce attacks is to ensure that users of the system, whether to receive data or to send data, are who they say they are. This has resulted in a range of authentication services being built for network users.

[0003] Authentication systems are typically incorporated into computer based communication systems to verify a user's right to access network resources. In a basic application when a user logs into the computer system an authentication process is initiated to verify the identity of the user. A common login process involves the entry of a password. The computer system compares the password with a stored list and, if the entered code matches the stored list, access is authorized. Conversely, if there is no match authentication is denied.

[0004] Basic password systems, although sufficient for low security related applications, do not provide the level of security needed for more sensitive

transmissions. The password may be stolen or may be replicated using a trial and error or dictionary approach.

[0005] Other authentication services such as biometric schemes i.e. iris scanning, use multiple factors to authenticate users as when using smart cards.

[0006] In a distributed system in which there are multiple servers and multiple authentication schemes it has been difficult to create a system which meets all the needs. For example, various applications may be running on different network elements and network management platforms wherein there is a need to provide identification and subsequently authentication of end user operators in order to perform access control to the network infrastructure. One solution consists of delegating the authentication to a third party entity so that the "a-priori" untrusted operator cannot fake the authentication process. In other cases the authentication policy is implemented on a per-application basis so that the operator needs to authenticate against different authentication mechanisms. This typically means that the mechanism used to achieve user authentication must rely on distributed devices that cannot be accessed directly using classical on the wire protocols.

[0007] An example of a prior art authentication systems is discussed in a Sun White paper entitled "Making Log In Services Independent of Authentication Technologies" by Samar and Lie. This paper describes a system wherein the authentication policy is enforced on the machine hosting the user to be authenticated. The solution makes use of a pluggable authentication module (PAM) to switch from one authentication backend to another. Using this mechanism the overall authentication process takes place locally at the user's work station. Since it does not make use of a trusted third party entity this solution does not fit in a general use case where the host is not trusted.

[0008] A second prior art solution is described in a technical white paper dated March 2003 entitled "Sun One Identity Server Overview". This solution makes use of a dedicated authentication server which allows a dedicated application server to handle incoming authenticated requests. The server maintains a trusted relationship with the user.

[0009] A similar system is described in U.S. Patent 6,510,236 which relates to an authentication framework for managing authentication results from multiple authentication devices. For each type of authentication device a device authentication server verifies that the data is acceptable.

[0010] These solutions generally solve the security issues inherent in the first prior art solution. However the solutions are not sufficiently flexible to handle a wide range of authentication schemes that could potentially be distributed across various elements of the network. In addition, these mechanisms and in particular that taught in the first prior art may be subject to tampering by an attacker.

Summary of the Invention

[0011] Accordingly, there is a need for a dedicated authentication server that performs the authentication of a end user. The server should be able to act transparently from the client's perspective to provide authentication services for a distributed system. The present invention provides this through the use of an authentication stack which has entries that trigger local or remote specific authentication actions to provide respective results which, when consolidated determine an authentication status of the end user client. Preferably, the authentication is created based on an authentication domain ID specified by the end user client.

[0012] Therefore, in accordance with a first aspect of the present invention there is provided a method of authenticating an end-user client in a computer-based communication system comprising the steps of: sending, by the end-user client, an authentication domain identifier to an authentication server; creating, by the authentication server and depending on the authentication domain identifier, an authentication stack comprising one or more stack entries; rendering, for each stack entry and depending thereon, an authentication service to produce an authentication result for that entry; and consolidating authentication results to obtain an authentication status for the end-user client.

Brief Description of the Drawings

[0013] The invention will now be described in greater detail with reference to the attached drawings wherein:

[0014] Figure 1 illustrates the basic components of the authentication framework according to the present invention;

[0015] Figure 2 is a flow diagram of the overall authentication process;

[0016] Figure 3 illustrates the invention in a per distributed application basis; and

[0017] Figure 4 illustrates a deployment use-case of the authentication stacks.

Detailed Description of the Invention

[0018] Figure 1 shows the basic components of the authentication framework according to the present invention. Using the framework an end user is able to authenticate through a stacking mechanism. As shown in Figure 1 a client on log in sends a message such as an authentication domain ID to an authentication server. A server builds an authentication model stack configuration which

provides a profile of the client based on the authentication domain ID. Through the authentication stack the authentication server is able to seek authentication through either remote authentication modules or local authentication modules. Each time a user triggers the authentication service the server creates a new authentication stack. Each element in the stack refers either to a local or to a remote module. Some of the entries of the stack may have been configured such that they are unable to render an actual authentication service but in fact trigger an authentication component that is remotely deployed. The processing of this remote component will create the actual authentication context necessary to handle the user authentication process on a specific authentication device. The authentication devices may be one of various biometrics schemes or it may be a cryptographic hardware service or appliance or it could be a smart card, USB token etc. The main authentication process that sits on the authentication server consolidates the results that it gets back from all of the virtual stack entities. It combines the consolidated results with the stack entries bound to the local authentication modules in order to reconstitute the entire authentication stack.

[0019] Figure 2 is a flow diagram that sets out the overall authentication process flow.

[0020] First the client to be authenticated sends to the authentication server a so called authentication domain ID that could be, for example, an application service identifier. The authentication server builds the authentication stack according to the configuration defined by the specific ID. Hence, a direct mapping must be explicitly defined on the authentication server to map an application ID with a list of software modules. An example of the configuration could be:

-Application1

RADIUSmodule

OSmodule

-Application2

SMARTCARDmodule

OSmodule

KERBEROSmodule

[0021] At initiation of the authentication process each entry in the authentication stack is processed. If the entry is mapped to a local authentication module the authentication process is performed locally. Otherwise the authentication server triggers a remote authentication module which retrieves authentication data from its local authentication device. Once all the stack entries have been processed the authentication server consolidates the results. If the authentication is successful a unique session identifier characterising the authentication session is sent back to the client. Otherwise, the client is notified by the authentication server that the authentication process is failed.

[0022] Figure 3 illustrates that by using the authentication stack module it is possible to reach different modules located on different applications running on different levels of the management network depending on the specific application. Thus, the solution provided by the present invention is easily deployed on a per distributed application basis. The solution leverages authentication synchronization capabilities into distributed environments where various software components using different authentication techniques need to share a common user authentication session. Thus the authentication requirements could be different depending if it is an alarm manager or more specific to the element management.

[0023] As shown in Figure 3 the client operator connects to the network management system which runs the authentication server. The authentication

server triggers the authentication module that sits on the client and this could be OS, USB-tokens, smartcards etc. It then triggers the Element Management System (EMS) authentication module which may be running for example on an element management system. Then it would trigger authentication modules that are running on the network element relaying the request to a remote authentication server such as radius.

[0024] Figure 4 exemplifies a deployment use case of the authentication stack in the course of an authentication process. In this case the client authentication involves different steps. A dedicated authentication module that sits on the client handles the operating system based authentication and retrieves OS credentials of the current logged in user. A server component handles directly the RADIUS based authentication and a smartcard authentication module handles authentication requests on the client side. The authentication module retrieves user credentials thanks to its direct access to the local smartcard reader appliance. An LDAP (lightweight directory access protocol) module that sits on a specific network element handles the authentication requests and access to the LDAP backend is performed through a dedicated LDAP module.

[0025] The solution provided by the present invention provides a flexible manner of aggregating various kinds of authentication mechanisms relying on different network nodes into a centralized authentication stack. In addition to greater flexibility the compartmentalised nature of the solution makes the initial configuration and subsequent maintenance of authentication modules easier than the prior art approaches. Furthermore, the versatility of such a framework allows reconfiguration of authentication modules in a seamless way from an end user standpoint. The versatility of this framework is inherent to the distributed authentication stack entries. Hence a security administrator is able to deploy

remote authentication indifferently through the network premises and into the core telecom infrastructure as well.

[0026] The solution requires the establishment of a secure channel between the client and the authentication server. Depending on the mechanism used this can introduce the requirement to provide extra resources both by the client and by the authentication server which may delay somewhat the overall authentication process.

[0027] Although specific embodiments of the invention have been illustrated and described it will be apparent to one skilled in the art that numerous changes can be made without departing from the basic concept. It is to be understood, however, that such changes will fall within the full scope of the invention as defined by the appended claims.
